# Aim

Ceramides can be identified in high resolution instruments, by top-down (from the intact precursor mass) or bottom-up (from MSMS) experiments in both positive and negative ion mode. We propose that the correlation of quantitative profiles from these 4 orthogonal and complementary identification identification strategies increases the confidence by decreasing the false positive identifications.

# Introduction

- Lipidomics lacks consensual criteria for reliable lipid identification and quantification. This contributes to **poor inter-laboratory concordance** of lipid profiles.
- Ceramides are prone to false positives due to the relative simplicity of their atomic composition.
- structural variability Ceramide impacts fragmentation pathways making the analyses of MS/MS spectra cumbersome in complex lipid extracts.
- In high resolution tandem mass spectrometers, lipid species of the same class can be identified and quantified in orthogonal and complementary ways.

# Methodology

### Automated Shotgun Lipidomic platform

- **Robotic sample preparation and infusion** for highthroughput analysis (200 samples/day).
- MS analyses in the **QExactive** allows:
- acquisitions in positive and negative ion mode with **fast** polarity switch
- fragmentation of all masses (DIA) from both polarities in less than 5 minutes.

# **Shotgun Lipidomics with High Analytical Confidence**

## Approach

#### Ceramide structure variability in mammalian cells

Ceramides in mammalian cells can be composed of sphinganine (18:0;2), sphingosine (18:1;2) or phytosphingosine (18:0;3) amide linked to fatty acids or alpha-hydroxylated fatty acids.

#### Ceramide ionization and fragmentation efficiency

ionization **ceramides** is Although the OŤ comparable in both polarities, the fragmentation is structure dependent so correction factors need to be calculated for accurate quantification.

# Application

MDCK cells are a model for epithelial formation. Ceramide remodelling is required in this process since the newly formed apical membrane is enriched in sphingolipids. It has been shown previously (Sampaio, et. al., PNAS, 2011) that, with the progression of polarization of MDCK cells, ceramides get longer and more hydroxylated but remained unclear if these changes occurred at the LCB or fatty acid level.

## Ceramide fragmentation in positive ion mode...

Fragmentation of ceramides in positive ion mode only provides structural information relating to the LCB. Moreover, the different standards show redundant fragmentation (e. g. m/z = 264.264) making it impossible to reliably identify and quantify the different ceramide backbones if they were to co-exist in the same sample.

Fragmentation in negative ion mo providing complementary structural and amide linked fatty acid (e.g. a3

#### Correlation of positive and negative ion mode data

We increased the number of identified species We increased the identification specificity by by 20% providing full structural characterization independent correlating profiles and of the ceramide molecules. observed that aprox. 30% of tentatively Ceramide remodelling occurred mainly at the matched lipids showed **poor correlation** and were discarded as false positives, leaving 31 long chain base. This **approach is generic** and can be **extended** consistently determined individual molecular to other lipid classes. species.
